Abstract

In the past 30 years, the notion of landscape has emerged in ecology as a result of both theoretical considerations and practical aspects of land use and land cover. This has generated a variety of numerical models addressing both methodological and thematic objectives. Scientists model landscapes for at least two reasons: to better understand the landscape dynamics themselves (called *intrinsic needs*) and to offer a realistic frame to support other ecological processes (*extrinsic needs*). This paper mainly concerns the intrinsic needs; it reviews and discusses the way the socioeconomic and/or ecological mechanisms of various landscapes have been explored through modelling approaches in the past. Our objective is to identify the possible lack of understanding in landscape dynamics and to propose a unified view of this complex object. We outline the links between the concepts of landscape and of models using a double-entry matrix, focusing on one hand on the four main terrestrial landscapes (agricultural, forested, arid and urban) and on the other hand on the main landscape model characteristics (explicit or neutral, patchy or continuous, and multi- or mono-scale).

The patterns and processes of each of the four landscape types, in particular, are analysed within a coherent framework. The heterogeneity of this yet coherent analytical matrix implies the need for unifying concepts and formalisms. The complexity theory and related concepts such as self-organization or formal grammar applied to landscape mosaics could help to further develop the mathematical formalisms necessary to assemble the various inner landscape processes. The discipline can now offer a theoretical dimension to dynamic landscape modelling aiming at understanding the mechanism unity underlying this complex object.

Article Revisions

Living Reviews supports two ways of keeping its articles up-to-date:

Fast-track revision. A fast-track revision provides the author with the opportunity to add short notices of current research results, trends and developments, or important publications to the article. A fast-track revision is refereed by the responsible subject editor. If an article has undergone a fast-track revision, a summary of changes will be listed here.

Major update. A major update will include substantial changes and additions and is subject to full external refereeing. It is published with a new publication number.

For detailed documentation of an article’s evolution, please refer to the history document of the article’s online version at <http://www.livingreviews.org/lrlr-2014-2>.

1 Introduction

Ecosystems are continuously changing in a way that is difficult to understand and to predict. Studies of climate changes (IPCC, 2007), land-use changes, biodiversity erosion (MEA, 2005), and energy management (Dalgaard *et al.*, 2006) would strongly benefit from models aiming at better handling landscape dynamics observed on continents (and in oceans). By landscape dynamics, we imply all kinds of land-cover changes occurring at mesoscale (tens of hectares or km²) on Earth. By models, we imply numerical (algorithm-based) and analytical (equation-based) approaches able to handle landscape elements and their dynamics. More precisely, a landscape is usually referred to as an object assembling elements of various natures (fields, forests, buildings, hedges, roads. . .) in interaction, simultaneously changing through many spatial and temporal scales (Forman and Godron, 1986; Turner and Gardner, 1991).

Scientists model landscapes for at least two reasons: to better understand landscape dynamics themselves (hereafter called *intrinsic needs*), and to offer realistic frames to host other ecological, biological, sociological and/or physical processes (*extrinsic needs*) (Rounsevell *et al.*, 2012). The role and status of models and modelling is itself an instantiation of a wider debate concerning representation and explanation (Clifford, 2007). For example, we may model urbanization and agriculture because they are two of the most important drivers of rapid changes in biodiversity worldwide (Benton *et al.*, 2002; Cincotta *et al.*, 2000). One of the advantages of studying landscapes as dynamic land covers is that models of this nature are not bound to some specific processes such as sectors of the economy or of biogeochemical behaviours. It helps to characterize the processes involved. Conversely, it is dangerous to infer landscape functioning on the sole basis of its observed structure (Schröder and Seppelt, 2006; Shochat *et al.*, 2006), as the pattern-process debate reminds it to us. This paper concerns intrinsic needs mainly, and reviews terrestrial landscape models (LM) from socio-ecological as well as methodological perspectives (Collins *et al.*, 2011).

Comprehensive studies state that agricultural landscapes today cover approximately 39–50% of continental areas (and are increasing), that forested landscapes still cover 30% of them and are rapidly disappearing, that urban areas (3–5%) and arid or semi-arid (15–25%) areas are continuously growing, too (Paudel and Yuan, 2012; Vitousek *et al.*, 1997). Numerous LM reviews may be found in the literature (Baker, 1989; Berling-Wolff and Wu, 2004; Scheller and Mladenoff, 2007; Verburg *et al.*, 2004), but each of them is focusing on one of the four main landscape types mentioned above. Yet, these landscape types are in deep interaction on continents (Lambin, 1997; Verburg and Veldkamp, 2004). Furthermore, it is to be expected that models used for one landscape type may be useful (or at least may feed concepts) for any of the other types. Can we identify common processes behind such landscape similarities and interactions?

In this discussion paper, we address the question whether it is useful and feasible to build a comprehensive theory of landscape dynamics; and in case of a positive answer, which concepts are today relevant for this program. Hence, our objective is to show the probable unity behind the landscape diversity and to advocate the urgent need of a comprehensive theory to handle this unity. We aim at offering a critical state-of-the-art by the use of a double-entry analysis grid (matrix), focusing on the one hand on the four main terrestrial landscape types and, on the other hand, on the most relevant LM characteristics we identified. About the latter, we discuss in particular explicit or neutral models (Gardner *et al.*, 1987; With and King, 1997), patchy or grid-based (Costanza and Voinov, 2004; Kotliar and Wiens, 1990), multi- or mono-scale models (Pascual and Guichard, 2005; Thomas *et al.*, 2008) and landscapes with or without linear networks (Proulx *et al.*, 2005; Pumain, 2006). We outline each case of this analysis grid by a list of associated processes and one or two examples described in more details, often taken from anthropogenic (i.e., man-made) landscapes. We then explore on the basis of this analytical grid which model characteristics would be useful for which landscape type. We did not intend to exhaustively compare papers dedicated to landscape modelling. We rather focused on theoretical and applied literature contributing to

this first proposal of a unified landscape dynamics theory.

We finally discuss a set of proposals on the basis of the previous landscape types and model characteristics that are presumably linked, and discuss the need for a comprehensive theory to interpret landscape dynamics (Lambin, 1997), as made by some authors for modelling scales and entities with LM (Agarwal *et al.*, 2002; Gaucherel and Houet, 2009; Haase and Schwarz, 2009; Verburg *et al.*, 2006). We more specifically insist on anthropogenic landscapes, for the main reason that these mosaics usually superimpose in a complex way human decisions concerning already present natural processes. Such a theory should be in the continuation of landscape ecology concepts (Forman and Godron, 1986), but based on original mathematical formalisms providing new insights for the land change science (Turner *et al.*, 2007). For example, it could be inspired from complexity approaches (Bolliger *et al.*, 2005; Crawford *et al.*, 2005; Solé and Bascompte, 2006). We discuss the implication of our suggestion for future research, which is needed to understand, predict and project the dynamics of these landscapes in relation to local and global environmental changes.

Table 1: The four main landscape types observed on continental areas (rows) are presented in regard to the dominant properties of their respective models (columns). The table lists occurrences that are frequent or scarce, focusing on: the presence of neutral models for each landscape type, the usual space representation, multilevel or multiscale models, the vein networks taken into account in respective models. We highlight *in italics* scarce intersections that are likely to be fruitful for landscape modelling and thus for landscape understanding.

Landscape types vs Model properties	Spirit (neutral models)	Space	Scales	Veins
Agricultural	Regularly explored	Often patchy	<i>Sometimes multi-level</i>	Often modelled, of various types
Forested	Regularly explored	<i>Raster</i>	Often multiscale	Of various types, yet rarely explicit
Semi-arid	Scarce	<i>Raster</i>	<i>Sometimes multi-level, yet not explicit</i>	<i>Scarce</i>
Peri-urban	<i>Scarce</i>	Sometimes patchy	Sometimes multi-level	Often modelled, of various types

2 Landscape processes: Current approaches

Here, we choose to review the four main landscape types of continental areas, continuously interacting. In particular, the increasing human demography shows specific trends on present landscape dynamics (Lambin *et al.*, 2001): forests landscapes are often replaced by agricultural or arid ones (Verburg and Veldkamp, 2004), agricultural landscapes are often replaced by urban or arid, partly depending on anthropogenic or climatic conditions (Figure 1). Yet, these transitions are not systematic at all. Only a few landscape transitions, such as forest shifting to agriculture, have been studied in depth up to now (Lambin, 1997; Usher, 1981), or shifts from rural to urban (Brown *et al.*, 2013). No exhaustive description of individual models is given here, while model comparisons are helpful to emphasize their respective drawbacks and advantages (Agarwal *et al.*, 2002; Haase and Schwarz, 2009; Mas *et al.*, 2014; Pontius Jr *et al.*, 2008). Instead, we present a representative list of processes concerned by each landscape type. Additionally, we systematically focus on one specific feature of each landscape type and on implementations for typical models of the domain.

2.1 Agricultural landscape

Agricultural landscapes are very much human-driven landscapes. Such landscapes are often studied using Land-Use and Land-Cover Change (called LUCC) models and are modelled as a selection of socio-economic and biophysical variables that act as so-called “driving forces” of land-use changes (Barton *et al.*, 2010; Matthews *et al.*, 2007; Verburg and Veldkamp, 2004). Land uses are simultaneously at the origin and results of land covers. Many models have shown that agricultural land covers are mainly driven by multilevel land-use processes, involving on the one hand behaviours of individuals and the upscaling of these behaviours, and on the other hand the macro-economic processes and their downscaled effects on landscapes (Thenail *et al.*, 2009; Willemsen *et al.*, 2012). Hence, micro-economic theory and general equilibrium modelling are often combined to model agricultural mosaics driven by isolated actors such as farmers and by regional or national economic incentives (Costanza and Voinov, 2004; Lambin *et al.*, 2000; Verburg and Veldkamp, 2004). Although biophysical factors mostly do not “drive” land-use changes directly, they can participate in land-cover changes (e.g., through climate change) and they influence land-use allocation decisions (e.g., soil quality) (Viaud *et al.*, 2010).

Land-cover patterns are influenced at different scales of analysis by different driving forces. At the local level, this can be the local water policy or the presence of small ecologically valuable areas, whereas at the regional level the distance to a market or an airport might be the main determinant of the land-cover pattern. There are various ways to model such agricultural landscapes, depending on the interaction between biophysical and socio-economic factors that for example may influence farming practices (field and farm levels), as collective actions (community and village levels) or as governance systems (district and province levels). The wish to merge these scales in causal relationships has recently led to two broad classes of agricultural LM: the top-down approach, based on remote-sensing and other data such as the CLUE-S model (Verburg *et al.*, 2002), and the bottom-up approach, based on local case-studies providing a refined understanding of human decisions such as the DYPAL model (Gaucherel *et al.*, 2006b, 2010; Valbuena *et al.*, 2010). However, we observed a limited understanding of the underlying mechanisms in the former approach and difficulties to generalize the findings due to the limited geographic coverage of the latter approach, thus justifying recent attempts to combine and even couple such approaches in landscape modelling (Brown and Castellazzi, 2014; Castella *et al.*, 2007; Houet *et al.*, 2010).

Many models have shown agricultural landscapes to be spatially driven by multi-level human decisions. We briefly illustrate this characteristic by highlighting a crop allocation system involving at least two successive organization levels (Castellazzi *et al.*, 2010; Gaucherel *et al.*, 2010; Thenail *et al.*, 2009): the patch level and the farm level. Agricultural landscapes indeed are often

Figure 1: Illustration of the two main landscape models. There are: process-explicit models, using specific processes (a), and neutral landscape models, using random functions (b). Process-explicit models often simulate landscape structure dynamics in terms of land cover (top-right), as well as bio-ecological and socio-economical processes (top-left) hosted by these structures. In addition, these processes are interacting (dashed arrows) through neighbouring fluxes that likely modify their dynamics (dashed curves). Neutral landscape models often simulate fixed landscape structures in raster mode (bottom-left), here adapted from Saura and Martínez-Millán (2000). To study agricultural landscapes some patchy neutral models (bottom-right), associated to linear networks (in black), have recently been built on the basis of Voronoi diagrams. Colours are representing hypothetical land covers.

composed of a wide variety of patches: crop fields, woodlots, hedgerows as well as roads, rivers and buildings, all influencing the farm property dynamics. Depending on the farm production system, the landscape is usually forced to follow a defined crop allocation at farm scale, which has been demonstrated to be the dominant driver of such human-based landscapes in temperate zones (Baudry *et al.*, 2003).

It may be relevant to focus on the pure temporal patterns observed within or between several farms that can be modelled by Markov chain models (Le Ber *et al.*, 2006; Usher, 1981). Conversely, spatial properties such as neighbouring fields appear to have a strong influence on the central patch studied, thus suggesting to focus on spatial as well as temporal patterns. Agricultural models have highlighted the interest of working with patchy mosaics, i.e., formed by mainly uniform, autonomous and contiguous patches, exhibiting sharp boundaries with their neighbourhoods (Kotliar and Wiens, 1990; Le Ber *et al.*, 2006). This new interest has furthermore focused modellers' attention on the deep distinction between the landscape composition (land cover) and landscape configuration (land-cover shapes and spatial arrangements) (Li and Reynolds, 1994).

2.2 Forest landscape

Forested landscapes proceed from different mechanisms. At large scales, modellers usually handle forest patches (woodlots), which exhibit very different types of vegetation cover, where forest would have been considered as a single land cover in an agricultural landscape for instance (Baker and Mladenoff, 1999; Perry and Enright, 2006; Scheller and Mladenoff, 2007). Many of the first forest models were "gap models" that operate at the scale of individual trees or small forest gaps or patches (Shugart, 1984). Forest parameters under study here may be the woodlot biomass, the tree density or height, the species composition or forest age, etc.

Models may also help here to better understand the effects of fire on forests, and in particular the role of landscape connectivity on fire spread, of fuel moisture content, of time since last fire, etc. (Keane *et al.*, 2013). Other models explore logging processes, by adjusting succession stages and transitions between communities in order to reach a particular forest state. Fire and logging are usually considered as disturbances of the landscape. In the more recent forest models, spatial interactions at and beyond the first-order neighbourhood (of an individual tree or a woodlot) are increasingly being taken into account.

The atomic entity of forested landscapes is the tree, therefore modelled by a combination of various processes such as phenology, growth and ecophysiological processes, dispersion, competition (inter- and intra-species), disturbances that may be natural (fire Finney, 1999; Keane *et al.*, 2013, herbivores Cousins *et al.*, 2003, pests, etc.) or human-based in the case of pruning or harvesting (de Coligny, 2006; Dufour-Kowalski *et al.*, 2011; Kurz *et al.*, 2000). For this landscape type, natural and human drivers are combined in complex harvesting, land-use and climate interactions.

One typical example of such processes involved in forested LM concerns seed dispersal (Cousens *et al.*, 2008; Wang and Smith, 2002). Attempts to model seed dispersal can be described by either phenomenological or mechanistic models. The former models mainly use Γ -function kernels describing installation probability at a certain distance to the mother-plant (Clark *et al.*, 2001; Saltré *et al.*, 2013). The latter dispersal models explicitly simulate grain (and pollen) dispersion depending on seed downfall velocity, of the height of seed release, of the structure of the local wind-field (in case of an anemochore species) or of animal movements (for zoochore species) that may promote long distance dispersal (Clark *et al.*, 2001; Nathan *et al.*, 2008). Models are particularly useful for highlighting the important role of long distance dispersal events to rapidly colonize new areas (Saltré *et al.*, 2013). LANDIS is a good example of the recent generation of forest models (Mladenoff, 2004), modelling dispersal as well as many other vegetation (either natural or anthropogenic) processes. Simpler models may help to analyze a more specific process (Seidl *et al.*, 2012; Usher, 1981). Deforestation is the most dramatic forest landscape dynamic and is, in most cases, the result of a complex causality chain, which originates beyond the forestry sector.

2.3 Arid landscape

Arid and semi-arid landscapes are subject to dryland degradation and vegetation transition processes (Lambin, 1997; Rietkerk and Van de Koppel, 2008). Water availability and thus climate forcing is the main driver of such landscapes, while most studies focus on the vegetation response to water resources. Dryland degradation may start with agricultural, forestry or grazing land-use intensification and proceed with more severe degradation factors among which are found soil erosion and soil salinization (desertification). Hence, arid landscape dynamics rarely are purely natural dynamics.

Other processes linked to disturbance caused by herbivores or fires have been studied in depth to understand arid landscape dynamics and to help predict the unwanted transition from a vegetated to a desert state (Scheffer and Carpenter, 2003). Drivers here are climate change impacting primary production of vegetation (Sankaran *et al.*, 2005), as well as socio-political mechanisms leading to a “pressure of production on resources” (Barton *et al.*, 2010; Krol and Bronstert, 2007). In most cases, we observe a somewhat complex interaction between natural and anthropogenic processes, such as in the desertification phenomenon (Lambin, 1997; Lejeune *et al.*, 2002). Many models help to address the questions why, where and when such arid landscape changes take place.

Some recent studies have explored a specific case of arid landscape dynamics involving binary states (vegetated and non-vegetated states) and two opposing forces of landscape shaping. It has been shown in particular that regular patterns may be the result of a competition force slowing down the vegetation colonization and a facilitation force favouring the same colonization trend (Couteron and Lejeune, 2001; Lejeune *et al.*, 2002). Competition for water resource through roots and facilitation against solar heat through the canopy act at different spatial scales, thus generating a wide panel of regular patterns (spotted or banded patterns, etc.).

Other studies at higher scales have shown that the size distribution of vegetation clusters in undisturbed plots follows a power law distribution (Scanlon *et al.*, 2007): most patches of vegetation have a small size, but a few of them have a very large size. Such self-organization pattern (i.e., landscape organization exhibiting a self-similar property, see Appendix A.2) seems to be the result of internal dynamic processes driven by local interactions, yet sometimes controlled by external factors such as precipitation (Rietkerk and Van de Koppel, 2008; Sankaran *et al.*, 2005). Such landscape functioning is still under debate and it is not yet clear how regular and self-similar patterns differ. As evidenced by the previous references, models in this landscape type are still often theoretical models.

2.4 Urban landscape

Similarly to agricultural landscapes, urban or periurban landscapes are mostly driven by humans (Berechman and Small, 1988; Berling-Wolff and Wu, 2004). The historical development of urban growth models are rooted in transportation and land-use planning. Early models postulated that the interaction between two cities and within a city varied directly with the size of the (two) city (cities), i.e., its demography, and inversely with the square of the distance between them (or the distance to its centre) (Foot, 1981; Lowry, 1964). The urban area was represented as a transport network and the flow and assignment of trips to the transport network modelled; later, more complex trips (home-work journeys) have been modelled and validated, even taking into account transport network congestion. In parallel, the idea emerged that trips and traffic in the city resulted mainly from decisions at the individual household level. At this stage, public policy impacts on household dispersion, employment constraints, urban agglomeration economics (and real-estate prices) and other land-use planning are analysed in various urban growth models (Gusdorf and Hallegatte, 2007; Gusdorf *et al.*, 2008).

As a relevant process in urban LM, we would like to consider urban growth with two different models. Interestingly, some cellular automaton models have emphasized the way in which locally

made decisions may lead to global self-organized urban patterns which are rarely, if ever, in equilibrium (Viguié *et al.*, 2014). For example, diffusion-limited aggregation models have been developed to handle rapid disequilibrium growth often due to the emergence of suburbs (Batty *et al.*, 1989; He *et al.*, 2013). Recent models focus on economics of agglomeration or ecological energetics, the flow of goods and resources in the city to better explain such disequilibrium. Cellular automata combining ideas of evolution, self-organization and fractal geometry enable to calculate transition potentials mimicking land-use changes by agents' behaviours (White and Engelen, 1993). These models have been found in good agreement with observations. Similarly, the FRACTALYSE model extends Christaller's Central Place theory according to a fractal (self-similar) principle, i.e., areas with smaller and smaller aggregated central places (Christaller, 1972; Thomas *et al.*, 2008). Such an approach indeed, enables optimizing urbanization processes by minimizing the use of places and buildings nearby places already occupied.

The concept of urban systems (i.e., multi-city urban networks) is complementary to that of urban growth and several models have documented and interpreted this concept (Pumain, 1989). After early models based on the central place theory, a second period of landscape modelling made a more explicit use of the networks, both in analyzing communication or migration flows between cities and by suggesting that networks were more efficient and more democratic forms of organization than hierarchies (He *et al.*, 2013; Proulx *et al.*, 2005; Pumain, 2006). Networks of innovation diffusion, inter-city migratory fluxes, urban competition, socio-economic trajectories of cities and comparative urban dynamics have become again implicit, but can help understand urban systems (Berling-Wolff and Wu, 2004).

3 Landscape-model properties: Current practices

Landscape models (LM) as defined here should not be confused with "landscape analysis models" aiming at analysing a spatial structure at landscape scales (Müller and Steinhardt, 2003). Instead, LM are dedicated to simulation of landscape change and dynamics. The previous section emphasises that many dynamic LM have been reviewed in the literature, concerning agricultural, forest, arid and urban landscapes (Berling-Wolff and Wu, 2004; Scheller and Mladenoff, 2007; Verburg and Veldkamp, 2004). LM mentioned in this paper are merely a sample selected to highlight some of the most important features of landscape modelling to explore some of the key challenges facing those who build and use LM. To be exhaustive, this section should also address considerations about the time management of models (Degenne *et al.*, 2009), about the 2D-3D representation of space in LMs (Gaucherel *et al.*, 2010), and many others. The time and spatial dimension challenges are urgent to improve our understanding of external needs such as biogeochemical processes, for example.

Scientific models pertain to various epistemological modes (Levins, 1966). They often serve an objective of comprehension through hypothesis tests and inference processes; they also help to define prospective objectives thanks to scenario elaboration and decision support tools; they finally offer a methodological objective by helping to define experiment protocols, by performing *in silico* experiments, by developing new algorithms and equations to fulfil a scientific questioning. In addition, another advantage of models is to integrate (to gather) knowledge into a coherent framework. We are not discussing here other topics concerning landscape modelling such as data calibration, validation, observation/simulation, comparison or sensitivity analyses. They are indeed critical in this debate about landscape modelling, but this would need another full-paper and has been well discussed in the literature (Jørgensen and Bendricchio, 2001; Mas *et al.*, 2014; Paegelow *et al.*, 2013).

3.1 Explicit versus neutral landscape models: the “spirit” of models

The first and probably main dichotomy observed in LM concerns process-explicit versus neutral models. Process-explicit models simulate landscapes by implementing one or several specific processes, such as in most of the previously mentioned models (Costanza and Voinov, 2004; Gustafson, 2013; Seidl *et al.*, 2012; Verburg *et al.*, 2004) (Figure 1a). Instead, neutral models are simulating landscapes with similar patterns and statistical properties without any process implementation (Gardner and Urban, 2007; With and King, 1997) (Figure 1b). Such models are more or less neutral, depending on the more or less extensive use of random functions to generate the pattern (see Appendix A.1 for details). Neutral LM offer some kind of null-hypothesis tests translated into the landscape dynamics topics. They help to answer the generic question: Does a random (or almost random) function simulate observed patterns (or not) and, more rarely, observed dynamics (Caillault *et al.*, 2013)? If so, it is maybe not necessary to combine complex landscape generation processes to interpret observed landscapes (Gaucherel *et al.*, 2006a; Saura and Martínez-Millán, 2000). Furthermore, if so, it becomes possible to model new *virtual* landscapes, dedicated to intrinsic as well as extrinsic needs already mentioned.

We have earlier detailed the kind of processes that are explicitly taken into account for LM, either of biophysical or socio-economical nature, and often both (Willemen *et al.*, 2012). A promising way of combining these various landscape processes certainly pertains to the use of model platforms in order to efficiently build models dedicated to landscape topics (de Coligny, 2006; Dufour-Kowalski *et al.*, 2011; Gaucherel *et al.*, 2006b) (Figure 2a). Another promising opportunity is that of Domain-Specific Language (DSL) (Degenne *et al.*, 2009; Fall and Fall, 2001). DSL are languages adapted to a specific target, such as modelling a broad class of landscapes, and sharing various methods and knowledge for this goal. They are almost all process-explicit models, with the exception of the RULES platform dedicated to neutral models (Gardner, 1999).

3.2 Raster versus patchy landscape models: the “space” of models

Another important dichotomy among LM, often mentioned but rarely discussed, concerns the type of spatial representation chosen to be implemented in the model. Most LM handle raster mode, i.e., grid-based or pixel-based, mosaics (Costanza and Voinov, 2004; Saura and Martínez-Millán, 2000), because pixels are easier to manipulate than the various objects found in the vector mode (i.e., polygons, polylines, points...) (Degenne *et al.*, 2009; Gaucherel *et al.*, 2006a). Yet, most landscapes, if not all, are patchy in the sense that they are composed of patches (polygons) that are considered uniform relatively to their main attribute (often land cover), with sharp boundaries separating them from the contiguous neighbours (Forman and Godron, 1986; Kotliar and Wiens, 1990). Such landscapes are often called categorical, as they suppose land-cover categories, with discrete states of patches. In a sense, landscape modellers realize that landscapes are often discontinuous and may be less efficiently handled by the classical tools developed for several decades, such as point-pattern processes, interpolations as Geostatistics, etc. New surface-pattern analysis and modelling tools are now able to handle highly non-stationary spatial structures (i.e., with variable statistical moments) (Gustafson, 1998; Li and Reynolds, 1994; Tischendorf, 2001). We list here a panel of advantages to model dynamic landscapes with patchy mosaics.

1. Realism – Among all advantages, the most convincing is certainly that patchy landscapes are more realistic. This argument is quite obvious for agricultural and urban mosaics, i.e., human-based landscapes (Forman and Godron, 1986; Kotliar and Wiens, 1990), but is still relevant for large forested and arid mosaics too, as we have seen that they often exhibit regular (and thus patchy) patterns, due to discrete soil, topography or climatic properties. Furthermore, this representation highlights existing boundaries between landscape elements. We argue here that the patchy representation, particularly suited for man-made landscapes,

may suit well to most natural landscapes too, considering their natural boundaries (Henne *et al.*, 2011; Moustakas *et al.*, 2009; Viaud *et al.*, 2010).

2. Complementarity – Patchy landscape simply is a new approach to study this object, thus offering an independent and potentially innovative way of studying the same object. Such independent ways of study have often been mentioned as useful to cross-check scientific interpretation. Manipulating polygons or polylines indeed suggests working with other unitary/single elements, computing and analytical methods, other topologies, etc. (Degenne *et al.*, 2009; Mackey, 2000). For example, polygons have at least as many neighbours as their numbers of edges, while pixels always have eight neighbours, presenting the same directions. This difference partly explains difficulties to handle vector mode objects, but also highlights the richness of this approach.
3. Qualitative view – A patchy approach is often more intuitive and more rapid than pixel-based approach once implemented, because it handles a single object (e.g., a polygon) instead of handling a list of non autonomous and/or non independent pixels being linked to artificially create the uniform polygon studied. As a corollary, the patchy approach enables working with much larger landscape extents or much more rapidly for a similar extent. Yet, possible drawbacks concern the need to model landscapes in a more qualitative view that is not always easy to handle (e.g., distance related questions such as pollen or gene diffusions).
4. Property control – Interestingly, the patchy concept finally helps to understand the difference between the landscape composition (land cover) and the landscape configuration (patch arrangement) (Li and Reynolds, 1994). In a grid-based approach, both are mixed and handled in a simultaneous way, because changing a pixel state changes its land cover simultaneously to the land-cover pattern with its neighbours. While landscape composition and configuration are not fully independent in a patchy approach, they appear to be sufficiently differentiated to understand whether the studied landscape process concerns purely attributive changes, such as agricultural successions (Castellazzi *et al.*, 2008; Verburg and Veldkamp, 2004), or is also modifying geometrical and/or topological changes, such as in urban systems for example (Pumain, 2006).
5. Object-oriented view – Similarly to remote sensing transition between grid-based and object-based detection, it is relevant in LM to manipulate objects (Flanders *et al.*, 2003). The patchy approach helps to dissociate objects within the landscape and to develop specific dynamical processes for them. Instead, a pixel is changing continuously from a crop field, a forest, a household, depending on probability transitions and thus is losing its nature all the time (Usher, 1981). Hence, patchy landscapes that are rather widespread and intuitive would possibly contribute to federate attempts directed towards the search for a general LM framework.

3.3 Mono- versus multi-scale models: the “scale” of models

LM often are multiscale, in a sense of including objects spreading over continuous scales or of including processes spread over several discrete organization levels. Multi-level models consider landscapes with two or more discrete organization levels such as temperate agricultural landscape processes mainly based on crop field rotations and farmer decisions. Other levels than farmers (villages, governments...) are often useful in modelling complex human-based landscapes. A more continuous view of scales, quite relevant in the case of natural landscapes (Pascual and Guichard, 2005), would probably be less appropriate and more difficult to implement in human-driven landscapes, due to our perception of discrete levels of actors in landscapes. It has been shown that crop allocation at the farm scale is responsible for most agricultural landscape patterns

(Benoît *et al.*, 2012; Houet *et al.*, 2010; Rizzo *et al.*, 2013; Thenail *et al.*, 2009). Studying the sole crop rotation is a fruitful approach when computed with Markov chains (Le Ber *et al.*, 2006), although we cannot ignore the spatial autocorrelation caused by farm management (Baudry *et al.*, 2003). This observation remains relevant for higher organization levels such as regional decisions, but today models rarely account for such multiscale/multilevel manipulations.

Vegetation cover in forested or arid ecosystems also shows various scaling behaviours. In particular, self-similar relationships between vegetation cluster size (scale) and their number (count) can define self-organized patterns of forested studied landscapes (Scanlon *et al.*, 2007). Several models such as in arid or forested areas have shown that local interactions may exhibit scaling laws over a wide range of conditions in arid areas, thus providing examples illustrating the criticality theory, i.e., discontinuous transitions between vegetated and non-vegetated zones (Pascual and Guichard, 2005; Rietkerk and Van de Koppel, 2008). Yet, such behaviours (Solé and Bascompte, 2006) are not convincing: first, they are not robust over scales (they concern only few orders of magnitude); second, they are not fully understood (for example the scaling exponent cannot be predicted by the originated processes); third, they are phenomenological and should still be related to the ecological processes involved (Gustafson, 2013); and fourth, if some processes (such as preferential attachment) have shown self-similar behaviours, it has not been proved that other processes would not succeed in doing so. In other words, this self-organization approach is close to a neutral model, but probably not fully appropriate for LM, as we think it will probably not provide in depth processes to understand landscape functioning.

3.4 Modelling networks or not: the “veins” of models

Agricultural and urban systems exhibit physical or more abstract linear networks in dynamic landscapes (Berling-Wolff and Wu, 2004; Turner and Gardner, 1991). Agricultural areas are for example characterized by the so-called “blue veins” constituted by river networks, and by “green veins” such as hedgerows and other grass margin networks that all have strong effects in the landscape generation and functioning (Thenail and Baudry, 2004). Fields and farms indeed are managed according to the islet they belong to, as farmers naturally follow these networks for defining their boundaries. Other networks (veins) are frequently found in rural areas, such as roads, dyke or ditch networks that may structure the landscape as well. Models have for example shown how a dyke network can influence the animal population viability it is hosting (Retho *et al.*, 2008).

Above all, the field mosaic itself is sometimes modelled by the use of a network, considering that each patch is characterized by a gravity centre (or a summit of a graph) and is linked to its neighbours (with the edge of the same graph) (Gaucherel, 2008; Le Ber *et al.*, 2006). Such linear networks can help to develop new analyses and to model tools as their objects have specific properties (Proulx *et al.*, 2005; Strogatz, 2001). They grow or divide in specific patterns and topological dynamics that are very different from point-patterns or surface-patterns already mentioned. Urban landscapes highlight in particular the role of hidden networks such as communication and transport networks. Phone, electric or energy (e.g., gas) networks may strongly structure the emergence of new households in suburban areas (Berechman and Small, 1988; Pumain, 2006). Transport networks, such as roads, railroads or tracks are also a strong constraint in the landscape dynamics (Forman and Godron, 1986).

4 What model characteristics for what landscape type: Research priorities

The appropriateness of model characteristics for modelling different landscape types has been rarely studied in detail. To combine the previous sections dedicated to landscape types and to LMs should help us to define research priorities in this field (Figure 1). For example, we mentioned that patchy models simulate agricultural landscapes, that neutral models are used to study forested landscapes, that multiscale models are applied to arid landscapes, and that urban landscapes are often modelled by taking into account various networks. Such approaches are not exhaustive. We question here whether further developments of the previous model characteristics for new landscape types would open fruitful and complementary avenues to the field.

1. Neutral models – Neutral models, acting as null-hypothesis tests, are useful to identify mechanisms responsible for the observed landscape pattern or, rather, for refutation of absent mechanisms (Gardner and Urban, 2007; With and King, 1997). It is often discussed how a specific process is able to generate a specific pattern, but it is more rarely tested how random or almost-random processes are not able to do the same.
2. Patchy models – A patchy approach is almost always possible to use, either according to some segmentation criteria or empirically and usually leads to a new conception of the studied landscape. Indeed, to use uniform patches with sharp boundaries between them is equivalent to discretize space in a specific way, radically different to that of more regular continuous or periodical representations (Gaucherel *et al.*, 2006a; Paudel and Yuan, 2012). This is obviously the result of approximations within each patch, never perfectly uniform, but this approach also enables better taking into account various “singularities” observed in real landscapes. Singular presences are common in human-driven landscapes, as humans usually differentiate land covers and avoid managing fuzzy boundaries. It is also relevant for natural landscapes (Levin *et al.*, 1993), in particular at higher scales, when smoothed (geological, lithological or hydrographical) boundaries between land covers are progressively reduced to a narrow line (Moustakas *et al.*, 2009; Viaud *et al.*, 2010). Fluxes or organism movements can be stopped at or redirected along these lines of highly irregular (non-stationary) zones, thus leading to new behaviours of involved ecological processes (Forman and Godron, 1986; Turner and Gardner, 1991).
3. Multiscale models – Multilevel and multiscale LM are being increasingly studied, but could be further explored in new contexts. While it is often easier to work at only one or two scales to simulate a pattern, the frequent roles of lower and higher scales have been shown in these pattern generations (called emergent or immergent). When scales are considered as discrete levels, the hierarchy theory has proposed a heuristic approach for many ecological and environmental studies (O’Neill *et al.*, 1986; Willemsen *et al.*, 2012). When scales are continuously successive, many concepts such as self-similarity (Pascual and Guichard, 2005; Scanlon *et al.*, 2007; Solé and Bascompte, 2006) or multifractality, and many tools such as geostatistics, wavelet transform (Grossman and Morlet, 1984), or local convolutions (Gaucherel *et al.*, 2008) have been developed in order to describe and sometimes to model them. Hence, such multiscale LM can be expected to flourish in the future.
4. Network models – Finally, linear networks are of a great importance in landscape dynamics. There are several reasons why they have not been studied in a similar extent to that of other landscape features: i) they are rarely the central object of landscape studies, far behind crop fields or tree stands for example (Forman and Godron, 1986); ii) reliable mathematical tools to handle networks such as graph theory have been considered only recently in environmental

sciences (Strogatz, 2001); iii) many ecologists were not sufficiently aware of the role of these linear elements before some studies showed how landscape structures are constrained by them (Proulx *et al.*, 2005). Studying relationships between a landscape and the networks that inhabit it (e.g., green veins, blue veins, or roads) will probably lead to new discoveries. In case of urban or agricultural mosaics, landscapes may sometimes be reduced to the sole network that is carrying most of the landscape information (Thenail and Baudry, 2004). Further, if we widen our considerations from linear networks to every kind of network, each landscape element can be considered as the node of a network, related to its neighbours by the network edges. Such topological network may be rich in information and interesting to study as such, opening new pathways to model landscapes (Gaucherel *et al.*, 2012).

5 Discussion: Towards a dynamic landscape theory

5.1 Universality behind case studies

On the basis of the landscape and model characteristics summarized in the previous sections, we suggest that there exists a profound unity between landscape-modelling case studies. Patchy structures, network roles and multiscale behaviours justify searching for a unified view of dynamic landscapes. The landscape concept is generic and the heterogeneity concept is universal. The central paradigm of landscape ecology is that the spatial structure of a landscape has an effect on the underlying ecological processes (Forman and Godron, 1986; Turner and Gardner, 1991). Some properties of the landscape such as heterogeneity, connectivity or fragmentation strongly influence the exchange and flow of organisms, matter and energy between the different components. From the start, deciphering the structural and the functional aspects of connectivity has been a challenge to landscape ecologists (Tischendorf and Fahrig, 2000) and discussions are still on-going. Moreover, this branch of ecology insists on the importance of scales and integration of processes (Dungan *et al.*, 2002).

Multiscale and network concepts, for example, are widespread and have recently appeared in the literature for a wide range of specific landscape studies (Caillaud *et al.*, 2013; Gaucherel, 2008; Thenail and Baudry, 2004). They offer opportunities for renewing the usual landscape ecology concepts (e.g., heterogeneity) that are no longer sufficient to understand complex and dynamic systems. Lambin mentioned that “the most fundamental obstacle to progress in the understanding and prediction of human impacts on terrestrial ecosystems lies in the lack of comprehensive theory and land-use changes” (Lambin, 1997). This remark, made for human-driven landscapes, may also be addressed to more natural landscapes: Do we today have at our disposal a comprehensive theory of land-cover dynamics? (Bolliger *et al.*, 2005). We have therefore to search for a common theoretical framework proposing coherent concepts and adapted formalisms to improve our understanding and modelling of landscape dynamics. From a more practical point of view, the UML (Unified Modelling language) emerged to provide a simpler and more universal language to model, but it remained poorly used in landscape modelling (Degenne *et al.*, 2009). The theoretical statement should not conceal the important role of data acquisition, without which no LM could exist, and the role of model application and validation in specific sites and dates. We are also conscious of the limits of describing ecological processes from landscape patterns in this way (Schröder and Seppelt, 2006). A theoretical framework for all types of terrestrial ecosystems, if any, should bear in mind such a debate and offer generic tools to bridge the gap between them.

5.2 Complexity theory as a conceptual basis

Awareness that a certain complexity was present in most landscapes has led to a holistic approach to landscape (Gallagher and Appenzeller, 1999; Looijen, 1998). The theory of complexity has shown

that the state and behaviour of certain systems does not result from the simple linear combination of the state and behaviour of its separate parts. Thus new properties are seen to emerge, which originate in the non-linearity and non-equilibrium of these systems (in thermodynamic terms). The study of these complex systems suggests holistic strategies that apply to landscape modelling as the landscape is a complex object (Bolliger *et al.*, 2005; Saltré *et al.*, 2013), which often has complex dynamics (Bürgi *et al.*, 2004). It shows emerging behaviours/patterns that are the result of complex interactions, such as diffusion or dispersal, crop allocation system or land-cover transition (time patterns), heterogeneous and multiscale growth of areas (spatial patterns), between its elementary/single constituents. If such processes seem very different, they may all appear for various situations and highly different landscape types. It is thus relevant to study them in unusual situations in order to trigger a possible unity hidden behind landscape dynamics of distinct types.

Landscapes are dynamical, a property that often remained understudied compared to the landscape pattern in itself. Some diachronic works intended to compare successive dates of these patterns (Kolb *et al.*, 2013; Mackey, 2000; Paudel and Yuan, 2012), but it was a preliminary task compared to complex, superimposed, multiscale and long term dynamics that are at play in every landscape. We now need to analyse these dynamics for themselves and ask related questions: Is a landscape stationary (i.e., with constant statistical moments) or does it present some discontinuities in time (Gaucherel *et al.*, 2012)? Is a landscape dynamic chaotic? Is it ergodic (i.e., with the same behaviour averaged over time as averaged over space)? What are its asymptotical states, if there are some (Gaucherel, 2011)? Does the landscape gather some conflicts (i.e., opposed changes of the same unit), for example between dynamics operating at different scales? We today need a conceptual shift to address these new issues.

Self-similar approaches in particular are in the vein of complexity theory, as they manage multiscale, non-linear and often out-of-equilibrium systems (Pascual and Guichard, 2005; Solé and Bascompte, 2006). Neutral and multiscale models are recent attempts to detect and quantify self-organization, while patchy mosaics and networks are well adapted to such attempts, too (He *et al.*, 2013; Paudel and Yuan, 2012). This explains why several scientists have begun to adapt these approaches to landscape studies (see Appendix A.2 for details), as mentioned in the previous section. Patchy and network systems are complex as they handle non-linear behaviour in space and time, for fluxes or movements that they shelter (Gaucherel, 2008; Proulx *et al.*, 2005). Hence, the four model characteristics detailed in this paper are well adapted to further develop a complex and unified view of terrestrial landscapes. They are probably not yet exhaustive, as specific temporal dynamics, driving forces, and spatial interactions of neighbouring or level of integration may be explored in more detail and compared between landscapes.

To go a step further, it has been mentioned that self-organization is a kind of optimization of the structure (D'Souza *et al.*, 2007). We propose here the hypothesis that every landscape is a structure optimized to better use (dissipate) its incomes (of energy and matter). Neutral LM may help to test this working hypothesis, by assembling various local and path-dependent processes (Brown *et al.*, 2005), i.e., depending on the previous time step (or steps) only, acting on patches, linear networks and point-patterns, and being finally optimized in order to fulfil the various constraints imposed to the landscape. Some recent illustrations of such landscape optimisations may be found in the literature (Gaucherel, 2011) and we recently explored this issue with the optimal control theory (Whittle, 1996) to summarize a landscape by defining its Hamiltonien function. This attempt proposes an appealing framework to improve our description of very different (yet, with common properties) landscapes. Such work is in the continuity of landscape ecology, as landscape heterogeneity may then be interpreted as a consequence of such optimization of land uses and/or land covers. In a sense, the landscape exhibits some properties close to that of living organisms, with changing, scaling, emerging and stabilizing patterns (heterogeneity properties) depending on its driving forces.

5.3 Mathematical formalism and modelling as a toolkit

To imagine new concepts is a prerequisite for developing a new dynamic landscape theory, but it will be necessary to simultaneously develop a mathematical formalism, in order to generically handle these concepts over a wide range of landscape types. There are very few attempts, to our knowledge, to formalize landscapes in terms of equations. The literature provides powerful Markov chains to manage landscape composition (Tepley and Thomann, 2012), under stationary and sometimes first order neighbourhood hypotheses (Le Ber *et al.*, 2006), while reaction-diffusion equations are sometimes able to manage landscape configuration, for natural and non-patchy lattices (Couteron and Lejeune, 2001). Yet, the coupling of landscape composition/configuration is rarely managed and agricultural or forested mosaics have not been set in equations. It is today a challenge for example to mathematically describe spatial autocorrelation of patchy and highly discontinuous patterns (Gaucherel, 2011; Levin *et al.*, 1993), in order to reveal hidden processes, to integrate them, to determine asymptotical behaviour or to predict landscape behaviour in alternative conditions. Here are the urgent issues of this formalization objective. Furthermore, the dynamics of such structures are still far from being mathematically described. For example, it is a challenging question to understand whether some landscapes are at equilibrium or not. The self-organization or optimization concepts have the advantage of offering coherent formalisms to handle various landscape types such as relatively continuous patterns. Statistical mechanics and optimal control theory (Whittle, 1996), may fulfil this requirement to open the way to holistic studies of landscapes.

A recent approach based on formal grammars, and in particular those related to graph rewriting-rules opens another track in this direction (Gaucherel *et al.*, 2012, 2010), especially for highly non-stationary (discontinuous in space and time) mosaics. Models based on formal languages, such as L-systems used in linguistics and biology (Lindenmayer, 1968a,b), develop objects using grammar-linked components to simulate automata: landscape patches are considered as words whose dynamics are described by a succession of rules that a grammar helps to formalize. It has been demonstrated that most patchy landscape compositional as well as configurational changes may be formalized by a combination of eight rules only: a landscape patch rotation, merge, split, dilation, erosion, appearance, disappearance and no change (Gaucherel *et al.*, 2012, 2010). This so-called landscape language has a flavour of universality and appropriately illustrates the possible unification of a wide range of landscape dynamics, be they patch, linear network or natural gradient changes.

Such kind of formalisms has the potential to widely spread into environmental disciplines. In a sense, they offer bottom-up approaches that require symmetrical top-down approaches, such as global optimization procedures, to complete our understanding of landscape dynamics (Castella *et al.*, 2007; Houet *et al.*, 2010). This is why it is still important to develop mechanistic models and to model contingent and specific processes (Gustafson, 2013), with local and Markovian rules. As a corollary, another challenge for landscape dynamic studies consists in developing model designs able to conciliate the rich ecological and socioeconomic knowledge we have with the requirement for formal models amenable to generalization across landscape types. Adequate methodologies such as platforms and domain-specific languages are at present under development to help this purpose (Figure 2b) (de Coligny, 2006; Degenne *et al.*, 2009; Fall and Fall, 2001; Gaucherel *et al.*, 2012).

6 Conclusion

Continents are undergoing rapid change. At fine scales, terrestrial landscapes are rapidly changing too, whatever they are, agricultural, forested, urban or arid. In addition, these four main landscapes are continuously meeting together in space and time, shifting from one of the previous types to another, under natural (climate change) and/or human driving forces (Figure 1). To benefit from a relatively unified theory of such landscape dynamics would help to better understand each of these landscape types as well as each observed landscape type transition. We have discussed here only intrinsic needs to understand the landscape object, but such a review can obviously also serve extrinsic needs: for example, population dynamics, fire and pest spread, human production systems, climatic influence are environmental processes that would all benefit from an improved landscape modelling. Such improvements in dynamic landscape theory and modelling would greatly facilitate the (weak or strong) coupling between terrestrial landscapes and species and would serve climate change and biodiversity assessments.

We are now starting to have powerful models to manipulate various landscape dynamics and to better understand their functioning. Landscape research offers several interesting concepts to understand landscapes, but such concepts are insufficiently adapted to recent modelling approaches. The intrinsic dynamic properties of landscapes, their multiscale properties, the network and patch interactions they inhabit are difficult to manage by the simple use of heterogeneity and fragmentation notions. To improve as well as to harmonise current landscape modelling, we propose in this review and discussion paper to explore several actions: i) to develop explicit process-based models, handling both natural and human driving forces, simultaneously to neutral LMs; ii) to favour the interaction of various landscape type models; iii) to develop patchy, network (of various types) and multiscale modelling; iv) and above all, to develop a coherent theoretical framework of dynamic landscape, on the basis of new and powerful neutral models and mathematical formalisms.

Acknowledgements

We thank C. Godin for having provided the Figure 2a. We warmly thank A. Cambien, A. Banos, J. Baudry, P. Couteron, and D. Lo Seen for their advice during the process of writing this paper. This synthesis was developed in the course of several projects funded by the Agence Nationale de la Recherche (projects “BiodivAgriM” and “INC”, ANR-biodiversité 2007, project “STAMP”, ANR-blanc 2007). We are thankful to anonymous reviewers for their helpful comments and suggestions on an earlier draft.

A Appendix

A.1 Neutral landscape models

Ecology is increasingly using “virtual” landscape modelling to evaluate the links between ecological processes and the spatial and temporal patterns they produce. *Neutral landscape models*, in particular, were designed to generate a landscape in the absence of a studied ecological process (Gardner *et al.*, 1987; Saura and Martínez-Millán, 2000). Unlike explicit LM that would simulate dynamic functions and relations between landscape elements, neutral models do not intend to produce the spatial pattern of any particular observed landscape. Neutral models deal more precisely with one or several characteristics of composition and configuration of real landscapes (Gaucherel *et al.*, 2006a; With and King, 1997). These models may belong to most of the above-mentioned landscape types (agricultural, forested, arid or urban mosaics). After comparisons with observed landscapes, spatial landscapes and structures simulated by neutral models can discriminate between influences likely to be caused by random (i.e., neutral) rather than real structures. Their contribution to landscape ecology has been extensive: development of spatial indices to describe landscape configurations, forecasting of configurations essential for ecological phenomena, definition of connectivity, understanding of landscape influence on animal species or seeds, development of a generic model of spatial complexity, identification of ecological consequences of spatial homogeneity. Many ecological applications for neutral models are found in studies on the dispersion and abundance of animal populations, forest fires or biodiversity (With and King, 1997).

There is a gradation of virtual landscapes, from the pure neutral model up to the almost explicit model (Figure 2). Landscapes simulated by neutral models are often pixel matrices (called raster mode) for which a land cover is associated to each pixel. In the simplest neutral model, random distributions of the two present classes are performed by associating each pixel with a probability of belonging to one of the classes. This simple model only constrains class densities (i.e., composition) and not their spatial distributions. The absence of spatial correlations in such models does not allow accounting for the complexity of real landscapes (Saura and Martínez-Millán, 2000). Although rudimentary, the random model has identified characteristics such as the critical value of the class probability beyond which certain properties (e.g., connectivity) of a simulated landscape are drastically different. More sophisticated, some configuration models also define a directional adjacency matrix Q . The Q_{ij} elements translate the probability of a pixel belonging to type i being adjacent to a pixel of type j , with adjacency possibly defined according to direction and distance (Gardner, 1999). These models can be refined by the modified random cluster method, which controls the shapes of simulated classes, by aggregating pixels together (Saura and Martínez-Millán, 2000). Many other neutral LMs have been proposed, for example on the basis of an iterative process changing some pixel classes, and thus leading to hierarchical or fractal patterns (Figure 2b).

All neutral models presented here deal with landscape considered as a continuous entity in raster mode, where the pixel is an autonomous (yet not independent) entity. Several ecological studies, however, need to represent landscape with a patchy map in which areas are considered homogeneous from the point of view of the ecological process studied (Kotliar and Wiens, 1990; Levin *et al.*, 1993). This becomes crucial in anthropogenic landscapes and those marked with linear networks (roads, rivers, hedgerows, etc.) or field limits. For this purpose, new neutral LMs have been developed (Gaucherel, 2008), which sometimes use a Gibbs algorithm to select patch classes or to draw linear networks. Furthermore, neutral LMs appear increasingly relevant as a basis to build a coherent theoretical framework for dynamical landscapes. By offering a null-hypothesis test, they help to discriminate between ecological processes and random functions. By handling more or less simple statistical equations to describe landscapes, they offer opportunities to capture patterns and/or dynamics within parsimonious and coherent formalisms.

Figure 2: Scheme illustrating the principle of a modelling platform (a) and the architecture of an example: the DYPAL landscape modelling platform (b). The principle of a platform aims at finding a compromise (the greatest common divisor GCD) between a range of models dedicated to various objectives and a universal model addressing all possible objectives (as the least common multiple LCM). A platform is built on the basis of a generic kernel (bottom, in blue) dedicated to the common object modelled (here patchy landscapes of the DYPAL platform), and then developed at low cost in various dedicated models (in warm colours).

A.2 Landscape self-organization

The concept of self-organization, inspired from the complexity theory and from physical systems, offers an appealing way for landscape modelling. By definition, a landscape would be called self-organized if at least one of its properties (e.g., the spatial distribution of tree densities) exhibits regular (i.e., with non random patterns at a specific scale) or self-similar (i.e., fractal, with a power-law scaling) behaviours (Rietkerk and Van de Koppel, 2008; Solé and Bascompte, 2006). The scientific community questions whether landscapes are often self-organized. If not, why? If yes, which ecological processes are responsible for the landscape self-organization?

The concept of self-organization has often been advocated to investigate ecological processes. For example, it has been observed that forested landscapes, both in temperate and tropical areas, sometimes exhibit self-organized patterns (Gaucherel, 2011; Scanlon *et al.*, 2007; Solé *et al.*, 1999). However, because it is still a phenomenological approach, self-organization is of little help to understand the forest functioning, and only provides a starting reference framework. By focusing on heterogeneous landscape dynamics, we wish to understand by which mechanisms (vegetation dispersion, competition, land-cover allocation...) self-organized structures emerge (Rietkerk and Van de Koppel, 2008; Solé and Bascompte, 2006). It is equally important to understand when self-organization fails to explain observed landscapes. What are the respective roles and weights of local rules (bottom-up controls), of more global rules (top-down controls), and of scaling properties in driving the fate of landscapes? What are the respective roles of human decisions and natural forcings? Under which conditions are simplified (yet realistic) landscape systems self-organized?

Two of the most common theoretical forest models exhibit self-organization and present interesting opportunities to understand complex landscapes: optimized and Turing-like patterns. On the one hand, recent studies have presented newly scaling properties for forested landscapes. Highlighting a link with optimal control theory and physical statistics, it is advocated that extended patchy forests may sometimes self-organize by optimizing the ecological processes involved in their generation. Preliminary forest models, based on a Hamiltonian or other summarizing functions of the forest element interactions have been developed in order to test the landscape self-organization hypothesis (Gaucherel, 2011; Lefever and Lejeune, 1997). On the other hand, Turing-like patterns concern periodical vegetation covers generated on the basis of opposite forces acting at different scales (Couteron and Lejeune, 2001; Lejeune *et al.*, 2002). A reaction-diffusion process or, analogously, a competition-facilitation process has already proven its ability to reproduce the properties of a large range of spotted, gapped or banded vegetation covers (Lefever and Lejeune, 1997; Lejeune *et al.*, 2002). Such vegetations appear to be self-organized too, yet on the basis of other patterns than the auto-similar properties mentioned earlier. By suggesting a relatively simple concept to describe landscapes, self-organization again offers opportunities to capture patterns and/or dynamics within parsimonious and coherent formalisms.
